Introduction

It is known that myocardial ischaemia and infarction leads to severe metabolic and electrophysiological changes that induce silent or symptomatic life-threatening arrhythmias. Sudden cardiac death is most often attributed to this pathophysiology, but many patients survive the early stage of an acute coronary syndrome (ACS) reaching a medical facility where the management of ischaemia and infarction must include continuous electrocardiographic (ECG) and hemodynamic monitoring, and a prompt therapeutic response to incident sustained arrhythmias. During the last decade, the hospital locations in which arrhythmias are most relevant have changed to include the cardiac catheterization laboratory, since the preferred management of early acute ACS is generally interventional in nature. However, a large proportion of patients are still managed medically.

Both atrial and ventricular arrhythmias may occur in the setting of ACS and sustained ventricular tachyarrhythmias (VAs) may be associated with circulatory collapse and require immediate treatment. Atrial fibrillation (AF) may also warrant urgent treatment when a fast ventricular rate is associated with hemodynamic deterioration. The management of other arrhythmias is also based largely on symptoms rather than to avert progression to more serious arrhythmias. Prophylactic antiarrhythmic management strategies have largely been discouraged.

Although the mainstay of antiarrhythmic therapy used to rely on antiarrhythmic drugs (AADs), particularly sodium channel blockers and amiodarone, their use has now declined, since clinical evidence to support such treatment has never been convincing. Therapy for acute coronary syndrome and arrhythmia management are now based increasingly on invasive approaches. The changes in the clinical approach to arrhythmia management in ACS have been so substantial that the European Heart Rhythm Association, the Acute Cardiovascular Care Association and the European Association of Percutaneous Cardiovascular Interventions established a task force to define the current position.

Mechanisms of ischaemia-related ventricular arrhythmias

Generation of the ventricular action potential by voltage and substrate dependent ion currents is the basis for the contraction of
each individual myocardial cell. This ionic balance can be disturbed by insults, such as ischaemia/reperfusion.

Arrhythmogenesis early in the course of an ACS, manifested as often polymorphic ventricular tachycardia (VT) or ventricular fibrillation (VF) is observed in a minority of patients with acute ischaemia and is often associated with genetic predisposition. Incidence of in-hospital mortality due to acute heart failure or VT/VF has declined markedly with the widespread use of reperfusion strategies. Acute myocardial ischaemia leads to adenosine tri-phosphate deficiency, anaerobic glycolysis causing acidosis, elevation of extracellular potassium (K⁺), and lysophosphatidylcholine accumulation. This multifactorial sequence of events results electrophysiologically in (i) ionic imbalance: (a) shorter duration of the action potential by activation of the substrate related potassium current: I_{K(S)}, and (b) less reduced resting membrane potential through inhibition of the inward rectifying potassium current: I_{K1}; (ii) less contractile force by events that culminate in the mishandling of intracellular calcium (Ca²⁺); and (iii) a reduced conduction velocity because of less functional gap junctions.

Myocardial reperfusion may cause profound electrophysiological alterations, dependent on the prior duration of ischaemia. A VT occurs more frequently with increasing duration of ischaemia, but later in the course of an ACS, and with extensive myocardial damage, the incidence of VT declines. Important contributors involved in arrhythmogenesis are the Na⁺/Ca²⁺ exchange pump, the slowly activating delayed rectifier K⁺ current and phosphorylation of sarcoplasmic reticulum proteins by CAMKII (calcium and calmodulin-dependent protein kinase II). The intracellular Ca²⁺ overload (among others caused by reactive oxidative stress) will result in spontaneous Ca²⁺ oscillations (calcium overload paradox) that trigger early and delayed after depolarizations induced ectopic beats. In addition, they will contribute to spatial and temporal dispersion of repolarization (variation in the action potential duration) and to re-entrant arrhythmias based on unidirectional conduction block, fractionation of cellular electrograms, and short action potential durations. For arrhythmic mechanisms, the currents flowing from the ischaemic/reperfused to the non-ischaemic zones are most important.

The mechanisms responsible for the initiation of these VA may differ based on the underlying disease (Figure 1): (intramural) re-entry in ischaemia, whereas triggered activity appears to be the dominant mechanism in reperfusion. Also when looking at the responsible mechanism for VT perpetuation, their role may differ but they contribute both to the severity of the arrhythmia and to sudden cardiac death.

Incidence, predictors, and outcomes of sustained ventricular arrhythmias in patients with acute coronary syndrome

Sudden death due to sustained VA is common in patients suffering from an untreated myocardial infarction (MI). In fact, electrical cardioversion (CV)/defibrillation and management of acute volume overload were the principal life-saving measures in the coronary care units before the advent of reperfusion therapies, beta-blockers, anti-thrombotic therapy, and statins. The electrical changes in acutely ischaemic myocardium, and especially in the border zone of an evolving MI, initiate and maintain these arrhythmias (see above). Prompt and adequate revascularization therapy, usually by interventional reopening of occluded vessels and stabilization of the culprit lesion with a stent, combined with initiation of adequate secondary prevention therapies (statin, dual antiplatelet therapy, beta-blockers, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers) aimed at preventing subsequent acute coronary events, have markedly reduced these life-threatening events in modern coronary care units. Patients who present with sustained VA in the first few days after a MI can hence be characterized by the following features, summarized in Figure 1:

1. Late presenters (i.e. patients in whom reperfusion therapy was delayed due to an insufficient chain of care from first onset of symptoms to transfer to an acute coronary care centre, or long patient-related delay, severe acute ischaemia in Figure 1).
2. Patients in whom revascularization was not or only partially successful due to technical difficulties (severe acute ischaemia in Figure 1).
3. Patients who carry an arrhythmogenic substrate prior to the acute event, either due to a prior infarction or due to a predisposition to electrophysiological instability (‘pre-existing myocardial damage’ in Figure 1).

Late presenters

Even in highly developed healthcare systems, only 70–80% of patients who present with ST-elevation myocardial infarction (STEMI) receive reperfusion therapy. Some patients never reach out for help to the healthcare system, while the diagnosis is delayed in others. Yet others will present with VF or syncope as the initial sign of the acute event, necessitating adequate resuscitation. High maximal creatine kinase (CK) values, Q waves on the ECG, markedly reduced left ventricular (LV) function in the sub-acute phase after a MI and a long history of symptoms attributable to the infarct prior to first treatment are good markers for these patients once they have reached the hospital. Patients at high risk in the setting of an ACS, easily assessed by clinical risk scores such as GRACE or TIMI, are likely to suffer from larger myocardial damage, especially when the ECG shows prominent ischaemic changes, the patient presents with persistent symptoms after initiation of therapy, or CK/troponin release patterns suggest extensive myocardial damage. These patients are at increased risk of sustained VA.

Incomplete revascularization

Rapid revascularization of the culprit lesion is often feasible, but may sometimes pose technical challenges, e.g. in highly calcified or bifurcated lesions. Furthermore, about 30–40% of STEMI patients and 70–80% of those with STEMI and cardiogenic shock present with a relevant stenosis in the non-culprit vessel. These patients remain at risk for recurrent ischaemic events even after the acute revascularization procedure and seem to be at increased risk for sustained VA. A careful review of the coronary anatomy can identify these patients. Emerging data suggest that early completion of revascularization may be beneficial, but further data are needed.
Arrhythmogenic substrate prior to the index event

Most patients survive their first ACS. Owing to progression of atherosclerosis, a second acute event will often occur despite maximal preventive therapy. Patients who suffer from an acute coronary event with pre-existing reduced LV function and myocardial scars are at risk for sustained VA in the acute and sub-acute phase of MI. Echocardiographic signs of markedly reduced LV function or ECG signs of an old MI can identify such patients. Furthermore, patients with increased sympathetic activity, or taken to the extreme of cardiogenic shock, are at increased risk of sustained VA in the setting of a ‘recurrent’ acute coronary event. Recent evidence
supports the assumption that sustained VA in the setting of an ACS is also dependent on an individual genetic predisposition to such events. This is most obvious in patients with inherited cardiomyopathies that confer electrical instability (Figure 1).

Antiarhythmic drugs are widely used, but are of modest efficacy and have important side effects. Only sparse data exist to guide AAD therapy for sustained VA related to ACS. However, overwhelming data exist that have shown the potential harm of most AAD therapy for patients with ischaemic heart disease. Nevertheless, even with the advance of non-pharmacological treatment options as catheter ablation, temporary or chronic AAD therapy may still be considered for the treatment of refractory VA. Initial attempts to tackle VT/VF in ACS, even when recurrent, should be electrical CV/defibrillation. Antiarhythmic drug treatment should be considered only if episodes of VT/VF are frequent and can no longer be controlled by successive CV/defibrillation. Especially in patients with recurrent VT/VF triggered by PVCs arising from partially injured Purkinje fibres, catheter ablation has been shown very effective and should be considered (see catheter ablation in ACS).

Lidocaine is a class I AAD that may reduce the incidence of VA related to myocardial ischaemia, although no beneficial effect on early mortality has been demonstrated. Because of potential proarrhythmia, with a trend towards excess mortality, prophylactic treatment with lidocaine has largely been discouraged. On the other hand, prophylactic treatment with lidocaine after cardiac arrest and successful resuscitation has shown significant beneficial effects for both, recurrence of VA and survival. However, others reported a lower risk of death at 24 h after thrombolysis and prophylactic lidocaine and a neutral effect on overall mortality. Recent analysis of GUSTO IIB and III studies has shown reduced early mortality in patients with VF/VF after acute MI and a neutral effect on 30-day mortality.

Considering the overall efficacy and side effects, lidocaine should be considered as an AAD for the acute intravenous management of recurrent VT/VF in ACS.

Amiodarone is a class III AAD with multiple additional electrophysiological properties. When AAD therapy is necessary in patients with severe structural heart disease, amiodarone may have the most balanced efficacy-to-risk profile. In a pooled database from two similar randomized clinical trials (the European Amiodarone Myocardial Infarction Trial and the Canadian Amiodarone Myocardial Infarction Trial), that evaluated use of amiodarone in primary prevention in patients recovering from MI, cardiac death and arrhythmic death or resuscitated cardiac arrest were significantly lower in patients receiving amiodarone, compared with placebo, if they were also receiving beta-blockers. There appeared to be no benefit of amiodarone over placebo in patients not receiving beta-blockers. However, even amiodarone treatment resulted in excess mortality when given over long periods to patients with advanced heart failure. It belongs therefore to the few AADs that are considered to have no or little effect on long-term prognosis when given to patients with severe structural heart disease and/or extensive MI. In the context of ACS, amiodarone therapy—compared with lidocaine—retrospectively has shown an increased short- and long-term mortality. On the other hand, in the setting of out-of-hospital cardiac arrest, amiodarone was associated with better survival to admission rate as compared with lidocaine in patients with refractory to shock therapy VF. Amiodarone should be considered for the
suppression (intravenous or oral) and prevention (oral) of recurrent arrhythmias along with beta-blockers.

Flecainide, propafenone, and ajmaline exert their antiarrhythmic potential by significant slowing of conduction. In the setting of ACS, these effects may result in aggravation rather than termination of VT/VF. The antiarrhythmic potential of these AADs for the suppression and termination of VA has been mainly studied until the 1990s.34–37 However, in the setting of ACS, these drugs may cause an aggravation of VT/VF. After the publication of the CAST trial that has shown an increased mortality in patients after MI treated with encainide, flecainide, or moricizine as compared with placebo, further research to class I AAD and VA has largely been abandoned.38 Thus, these drugs should not be used in ACS.

Dofetilide and azimilide are class III AADs that prolong cardiac repolarization and refractory period with proven efficacy on the suppression of VA.38–40 The treatment with azimilide did not affect the mortality of patients with a recent MI and an LV ejection fraction of 15% to 35%.41 Only few data exist on the use of dronedarone for the treatment of VA; however, an increased mortality has been reported in patients with AF and heart failure treated with dronedarone.42 All class III AADs increase the QT interval with a risk for torsade de pointes tachycardias. However, none of these drugs had been specifically investigated for the treatment of VA related to ACS and can thus not be recommended for this indication.

document image
deliver ATP for VT faster than 200/min is safe, reduces the need for shocks and improves mortality compared with conventional therapy. The number of VT cycles needed for detection can be increased from nominal values to allow spontaneous termination, and sustained rate duration should be prolonged or disabled. Redetection can carefully be prolonged to reduce the risk of inappropriate detection of non-sustained VT in many patients. In some cases, it may be advisable to turn off the ICD in order to avoid multiple ineffective shocks provided that the patient is strictly monitored in an intensive care unit and that CV/defibrillation might be provided in a timely fashion in case of life-threatening arrhythmias.

On the basis of the observation that VT tends to be abrupt in onset and somewhat regular (high stability), sinus tachycardia tends to accelerate gradually, and AF is irregularly irregular (low stability), it was found that programming sudden onset and stability criteria helped to discriminate supraventricular arrhythmias and reduced the risk of inappropriate shock. In addition, just as the surface QRS complex during VT generally differs from that during sinus rhythm, discrimination algorithms can be used.

Radiofrequency ablation of PVC originating from the Purkinje fibre network holds great promise in the treatment of electrical storm. The typical indication for ablation is VT refractory to medical therapy in patients who also receive multiple ICD shocks. In patients with electrical storm, catheter ablation should be considered as a treatment option at an early stage. Recurrent VT/VF and Electrical Storm in ACS

Figure 2

Treatment recommendations for recurrent VT/VF and electrical storm in ACS. ACS, acute coronary syndrome; ICD, implantable cardioverter-defibrillator; LVAD, left ventricular assist device; VF, ventricular fibrillation; VT, ventricular tachycardia.

Recommendations for management of electrical storm and inappropriate shocks in patients with acute coronary syndrome

- Initial management of patients with electrical storm requires identifying and correcting underlying ischaemia.
- Amiodarone, beta-blockers and electrolyte correction as needed form the cornerstone of antarrhythmic therapy.
- Patients who have implantable cardioverter-defibrillator may require device reprogramming.
- A focal rescue ablation approach targeting the trigger for ventricular fibrillation early after acute myocardial infarction seems promising (Figure 2).

Catheter ablation of sustained ventricular arrhythmias in acute coronary syndrome

Incessant sustained VA that occurs in ACS is a life-threatening condition, carrying a high morbidity and mortality rate. It can be difficult to control with AADs, as class I AADs and amiodarone efficacy in reduction of mortality is controversial and time is required for amiodarone to reach therapeutic levels to provide effective rhythm control. Catheter ablation of VA during the acute phase of an ACS is rarely performed, and most ablations for incessant VA occur post-MI. However, in patients with intractable, drug-refractory VA, catheter ablation after treating
the underlying ischaemia can play an important role and these patients should be referred to a specialized ablation centre.

The two main mechanisms implicated in the induction of sustained VA in ACS are macro-re-entry from heterogeneous substrate, and after-depolarizations and triggered activity from impaired but ischaemia-resistant Purkinje fibres within areas of myocardial ischaemia leading to PVC, and both can be targeted for ablation (Figure 3).

Radiofrequency ablation using an irrigated-tip ablation catheter, in conjunction with a 3D-electroanatomical mapping system is most commonly undertaken. This is done via either an antegrade transseptal, retrograde aortic or a combined approach. In the majority of cases due to the sub-endocardial location of the Purkinje fibres and the ischaemic myocardial substrate, endocardial mapping, and ablation suffices. Mapping of PVCs requires that they occur frequently during the electrophysiology procedure and ideally should be performed during an electrical storm, as usual pacing maneuvers and medications are often unable to initiate ischaemia-induced PVCs. Activation mapping can then be performed, while assessing for Purkinje potentials. These low-amplitude, high-frequency signals precede the ventricular extrasystole signal by up to 160 ms at the site where the culprit PVC originates, usually in the region of the ischaemic borderzone of the MI territory.

When spontaneous PVCs and VA are not seen, pace-mapping can be performed against PVCs recorded prior to the procedure; however, only when they are monomorphic in nature. Ablation endpoint is the suppression of the triggering PVC, as well as the loss of the Purkinje potential. Substrate-guided ablation using bipolar amplitude mapping, particularly in patients with un-mappable VA, has also been successfully reported, although the best ablation approach has yet to be defined. Ablation lines and clusters through areas of ischaemia and slow conduction to homogenize substrate, as well as circumferential ablation around substrate and substrate isolation have been described.

Reported acute success rates are up to 72%, with only 6% experiencing recurrence of VA storms. Recurrence occurred more frequently in patients with monomorphic VT electrical storm, as compared with those with polymorphic VT or VF. Recurrence was also significantly reduced only in patients where all VAs were suppressed during the ablation procedure, which has been shown to be a good marker of long-term success and survival.

Complications associated with catheter ablation of VA include cardiac tamponade, ischaemic stroke, atrioventricular (AV) block, valvular injury, cardiac decompensation, and death. Peri-procedural mortality is reported to be up to 3% in this sub-group of unstable

![Figure 3](http://europace.oxfordjournals.org/)  
*Figure 3* Ventricular tachycardia in a patient with an acute coronary syndrome: (A) repetitive monomorphic ventricular tachycardia two days after percutaneous coronary intervention of the circumflex artery in the setting of an acute coronary syndrome; (B) recurrent ventricular tachycardia induced by a monomorphic premature ventricular complex.
patients, and is mostly associated with uncontrolled, intractable arrhythmia. The long-term mortality post ablation is up to 18%, mainly due to VA and acute decompensated heart failure. In addition, ICDs have reduced mortality from VA due to myocardial ischaemia. However, it is also clear that both appropriate and inappropriate ICD shocks confer an increased mortality rate and reduced quality of life. Thus, early ablation of patients with electrical storm, which leads to significantly decreased recurrence rates for recurrent VA, should decrease long-term morbidity and mortality associated with ICD shocks.

Catheter ablation of VA in ACS should be recommended, particularly in electrical storm; however, due to the often hemodynamically unstable nature of these patients, it is a highly complex procedure with significant associated morbidity and mortality. Therefore, it requires highly trained electrophysiologists with an excellent knowledge base and experience in VT ablation and a high volume electrophysiological laboratory to perform such procedures. To facilitate this, a referral network similar to that for ACS should be established to improve patient access to such adequately equipped hospitals.

**Recommendations for catheter ablation of sustained ventricular tachyarrhythmia in patients with acute coronary syndrome**

- In patients with drug-refractory electrical storm, radiofrequency catheter ablation during an electrical storm is valuable in the management of sustained ventricular tachyarrhythmia (VA).
- Ablation endpoint is suppression of the triggering premature ventricular complex, loss of Purkinje potentials, and in un-mappable VA, substrate-guided ablation can be performed.
- Owing to hemodynamic instability, these complex procedures should be performed by experienced electrophysiologists.
- When no highly experienced operator in ventricular tachycardia (VT) ablation is available, early transfer to a high volume VT ablation centre should strongly be considered (Figure 4).

**Arrhythmias in patients undergoing primary percutaneous coronary intervention for ST-elevation myocardial infarction**

Arrhythmias and conduction disturbances are common during the early hours after an acute MI (Table 1) and a major cause of death in the pre-hospital phase. The occurrence at greatest frequency before or during primary percutaneous coronary intervention (PCI) indicates that ongoing myocardial ischaemia and reperfusion injury are major determinants for arrhythmias and conduction disturbances. Interestingly, larger infarct size is associated with occurrence of sinus bradycardia, accelerated idioventricular rhythm and sustained VT but not VF. During the primary PCI procedure, ventricular tachycardia and fibrillation should be managed according to ESC guidelines. In patients with cardiac arrest and who are unresponsive to conventional cardiopulmonary resuscitation, it is reasonable to use mechanical chest compression devices and emergency cardiopulmonary bypass support is reported to be feasible. In hemodynamically unstable patients with refractory incessant VT, percutaneous left ventricular assist devices (LVADs) may be appropriate (see

below). Following intervention, the incidence of arrhythmias ranges from 6% to 28% for new-onset AF, 7–13% for non-sustained VT, 5–10% for high-degree AV block (≤30 beats/min lasting for ≥8 s), 7%–16% for sinus bradycardia (≤30 beats/min lasting for ≥8 s), 5% for sinus arrest (≥5 s), 3–6% for sustained VT, and 3–6% for VF according to retrospective registry data or prospective recordings from cardiac monitors implanted soon during an acute MI.73

The occurrence of AF is frequently associated with severe LV damage and heart failure. Episodes may last from minutes to hours and are often repetitive. The arrhythmia is most often well tolerated and no specific treatment is required, other than anticoagulation. In some instances, the fast ventricular rate contributes to heart failure, requiring prompt treatment using direct current cardioversion (DCCV) with further management as indicated below. Several studies have suggested that development of AF in the setting of acute MI is an independent predictor of all-cause mortality, irrespective of the treatment given.74,75 Atrial fibrillation not only increases the risk for ischaemic stroke during hospitalization but also during follow-up, and this includes patients with paroxysmal AF that has reverted to sinus rhythm at the time of discharge. Accordingly, patients with AF and risk factors for thromboembolism should be adequately treated with oral anticoagulation. Because AF will generally require anticoagulation, when choosing a stent in these patients, the benefits of drug-eluting stents on restenosis should be weighed carefully against the substantial bleeding risks that are associated with the prolonged combination of triple antithrombotic therapy (see below). Other supraventricular tachycardias are uncommon and are usually self-limiting.

Ventricular premature beats are almost universal on the first day of the acute phase and more complex arrhythmias (multiform complexes, short runs, or the R-on-T phenomenon) are common. Their value as predictors of VF is questionable. No specific therapy is required.

The long-term prognostic significance of early (≤48 h) VF or sustained VT in patients with acute MI is still controversial. In the APEX-AMI trial, VT/VF occurred in ~6% of patients with STEMI presenting for primary PCI.15 Two-thirds of these events occurred before the end of cardiac catheterization (defined as early events) and 90% within 48 h. Ventricular tachycardia/VF was not benign and was associated with substantially increased morbidity and mortality. Some of this association was related to older age, greater prevalence of comorbid conditions, and adverse presenting and post-cardiac catheterization features (ST resolution and TIMI flow) as shown by the attenuation of the risk with adjustment of these factors in a multivariate model. However, even after accounting for these variables, any VT/VF remained associated with a more than 3-fold higher risk of 90-day mortality in patients undergoing primary PCI. The prognostic significance of late VT/VF appeared to be greater than early VT/VF with more than 5- and 2-fold higher risks of 90-day mortality, respectively. Thus, these data support the prognostic importance of (any, early, or late) VT/VF as an independent and incremental risk marker, although this does not prove a cause-and-effect relationship. However, sustained VT/VF after primary PCI in the HORIZONS-AMI trial was not significantly associated with 3-year mortality or major adverse clinical events.76 Clinical management of sustained VT and VF after primary PCI is according to ESC guidelines.7

### Arrhythmias in cardiogenic shock complicating acute myocardial infarction

Cardiac arrhythmias including VT/VF, AF, and conduction disturbances are common in patients with acute MI complicated by cardiogenic shock and are associated with high short-term mortality.77–81 Cardiogenic shock, acute ischaemia, and the use of inotropes are main risk factors for the development of arrhythmic events.81 Therefore, correcting factors underlying cardiogenic shock, substrate, and triggers for arrhythmia, play main role in their management.17,82,83

#### Ventricular arrhythmias

Sustained VT occurs in 17–21% and VF is seen slightly more often (24–29%) in selected patients with cardiogenic shock and acute MI, undergoing thrombolysis or primary PCI.77,78 In cardiogenic shock, sustained VT/VF might deteriorate hemodynamic status and LV dysfunction. The goal of therapy should be to restore the rhythm immediately to avoid hypoperfusion, which leads to end-organ damage. Regardless of the cause of cardiogenic shock, sustained VT/VF must be treated promptly with DCCV without hesitation. Catheter ablation may be indicated as a salvage procedure if VT recurs (see above).27 Antiarrhythmic therapy (usually intravenous amiodarone, lidocaine) and electrolyte balance correction could be considered if necessary for acute management.17 Care should be taken with intravenous amiodarone to avoid hypotension. For selected patients with refractory VT/VF and rapidly deteriorating hemodynamic and clinical status, implantation of percutaneous LVAD and extracorporeal membrane oxygenation (ECMO)-assisted primary PCI have been found promising as a bridge to recovery, in gaining time to implement and assist appropriate therapies and prolonging survival.84–86,93–95 Implantation of percutaneous LVAD (Impella 2.5 assist device) in patients with MI and cardiogenic shock, as well as presenting with cardiac arrest was accompanied by reduction of tissue hypoxia, hemodynamic stabilization, and improvement of neurological outcome.84,93,94 Extracorporeal membrane oxygenation-assisted PCI significantly improved recovery and survival of patients with cardiogenic shock and refractory VT/VF as compared with intra-aortic balloon pump (IABP) with 69.23% of...
patients successfully weaning off the support in the ECMO group and only 12.5% in the IABP group (P = 0.02). The latter is no longer recommended. The IABP-Shock II study demonstrated no beneficial effect of IABP on tissue hypoxia, time to hemodynamic stabilization, short- and long-term mortality in patients with cardiogenic shock as compared with medical treatment. Recent meta-analysis on the effect of IABP according to the type of reperfusion in patients with MI and cardiogenic shock showed overall no effect on the risk of in-hospital and long-term mortality and trend to higher risk of in-hospital death with IABP support in patients undergoing primary PCI [relative risk 1.18, 95% confidence interval (CI) 1.04–1.34]. Intra-aortic balloon pump is not expected to work in case of VF, as there is no circulation to augment.

Proper hemodynamic support with inotropes and vasopressors is required, though caution must be taken for dopamine use, since it increases risk of arrhythmias in patients with shock, which are less seen with other inotropes. Coronary reperfusion is key to improving survival. Recent pooled analysis of both the SMASH and SHOCK trials showed that in cardiogenic shock patients, early revascularization reduced risk of death by 18% (relative risk 0.82, 95% CI 0.70–0.96) compared with the initial medical stabilization. Therefore, early hemodynamic stabilization and arrhythmia management should not delay revascularization.

Atrial fibrillation

About 11–20% of patients with acute MI presenting with cardiogenic shock develop AF. Several mechanisms underlying cardiogenic shock can predispose to AF by creating either a substrate or a trigger for this arrhythmia. Hemodynamic changes as an increase in pulmonary capillary wedge pressure and left atrial pressure, can lead to AF. The adverse hemodynamic consequences of AF can quickly lead to a worsening of symptoms, which may be difficult to manage. Immediate DCCV should be performed to restore sinus rhythm and hemodynamic stability when cardiac output is compromised. Amiodarone intravenously can be used for acute rate control with caution of hypotensive effect. Though evidence on the efficacy of amiodarone in the setting of cardiogenic shock is limited, in one study of single bolus intravenous amiodarone use for acute rate control it also resulted in (delayed) pharmacological conversion to sinus rhythm. In patients with pre-existing AF on oral amiodarone therapy, it may also enhance success of DCCV. Other rate controlling agents must be avoided due to negative inotropic effects. In refractory cases, AV node ablation with biventricular or LV stimulation could be considered for rate control, as they have been found feasible in correction of hemodynamic derangement of patients with cardiogenic shock and severe heart failure.

Conduction disturbances

High-grade AV block and asystole develop in about 23–35% of acute MI patients with cardiogenic shock, especially in inferior infarctions with proximal right coronary artery (RCA) occlusion. The rate of complete heart block is much lower in adequately revascularized infarct patients, and prompt revascularization of the infarct artery should be attempted. Bradyarrhythmias are induced by either autonomic imbalance or ischaemia and necrosis of the conduction system (see section below). It is important to recognize which of them are transient and which are likely to progress to irreversible and symptomatic high-degree AV block, which has been associated with a mortality rate approaching 80% due in large part to greater loss of functioning myocardium. Temporary transvenous pacing is necessary for patients with severe and symptomatic bradyarrhythmias if they do not resolve within few minutes after reperfusion.

#### Recommendations for management of arrhythmias in cardiogenic shock complicating acute myocardial infarction

Regardless of the type of arrhythmia, treatment of the underlying cardiogenic shock with prompt revascularization should be done as the primary procedure and should not be delayed by arrhythmia treatment.

- Acute management of ventricular tachycardia (VT)/ventricular fibrillation (VF) in the setting of cardiogenic shock includes immediate direct current cardioversion (DCCV), amiodarone, lidocaine if necessary.
- Percutaneous left ventricular assist device and extracorporeal membrane oxygenation-assisted percutaneous coronary intervention can be used in case of refractory VT/VF.
- Catheter ablation may be considered as a salvage procedure if arrhythmia persists (see above).
- Atrial fibrillation should be managed by DCCV if high ventricular rate compromises cardiac output; amiodarone can be used for rate control and assisting cardioversion.
- Atriointerventricular node ablation with biventricular or left ventricular stimulation could be considered if above rate control measures fail.
- Severe and symptomatic bradyarrhythmias accompanied by hemodynamic instability require placement of temporary pacemaker if they do not resolve within few minutes after reperfusion.

#### Incidence, prognostic implications, and treatment of atrial fibrillation in patients with an acute coronary syndrome

Atrial fibrillation, the most commonly encountered clinical arrhythmia, often coexists with acute MI. Atrial fibrillation has been reported to complicate the course of acute MI in 2.3–21% of hospitalized patients. In recent years, the widespread use of early reperfusion therapy (thrombolysis and PCI) as well as the use of beta-blockers, angiotensin-converting enzyme inhibitors and angiotensin II inhibitors has led to a substantial decline in the incidence of post-MI AF. However, as the population ages and as AF increases with age, we can expect that AF will still remain a frequent and worrisome complication of acute MI.

Atrial fibrillation may already be present at the time of hospital admission for acute MI, or may develop during the hospital stay. Pre-existing AF accounts for approximately one third of all cases of AF observed in patients with acute MI, and new-onset AF for the remaining two-thirds.

Possible underlying mechanisms of AF in the setting of acute MI are atrial ischaemia or infarction, acute hypoxia or hypokalaemia, pericardial inflammation, increased LV diastolic pressure and left atrial pressure, hemodynamic impairment secondary to LV dysfunction and abnormalities of autonomic regulation. These mechanisms...
Cardiac arrhythmias in acute coronary syndromes

may be found alone or in combination, and may superimpose on predisposing diseases, such as previous cardiomyopathy, valvular disease, or chronic lung disease.

Once AF develops, usually there is a significant worsening of hemodynamics due to the high ventricular rate, irregular ventricular filling, and/or loss of atrial contribution to cardiac output.

Independent predictors of the occurrence of AF in acute MI include older age, elevated heart rates at admission, pre-existing AF, LV hypertrophy, presence of heart failure symptoms, and LV dysfunction. These risk factors have been described regardless of the type of reperfusion therapy (i.e. none, thrombolysis, PCI). Moreover, patients who develop AF more often have hypertension, diabetes, previous MI, multi-vessel coronary artery disease, higher levels of biomarkers of myocardial damage, and low TIMI 3 flow grade after reperfusion therapy.106,107

The prognostic impact of AF that occurs in the setting of acute MI is still controversial, with some studies describing an independent adverse effect on mortality and others failing to detect such an association.106 However, a recent systematic review and meta-analysis, including 43 studies and 278,854 patients, showed that AF carries an excess risk of in-hospital, short-term (<30 days), mid-term (>30 days to 1 year), and long-term (>1 year) mortality among patients with acute MI, with at least a 40% increase, regardless of the type of AF (pre-existing or new-onset). Increased risk included both sudden and non-sudden cardiac death. This worse prognosis persisted, in patients with new-onset AF, even after adjustment for age, diabetes mellitus, hypertension, prior MI, heart failure, and coronary revascularization.109 Moreover, according to a recent large community study, the mortality risk, in patients with new-onset AF, seems to be greatest when the arrhythmia develops later than 30 days post-acute MI [hazard ratio (95% CI) 2.58 (2.21 to 3.00) vs. 1.81 (0.45 to 2.27) for AF between 3 and 30 days, and 1.63 (1.37 to 1.93) for AF within 2 days].107

In addition to increased mortality, patients with acute MI and AF have also a higher incidence of re-infarction, cardiogenic shock, heart failure, and asystole, probably as an expression of the more severe impairment of coronary circulation and hemodynamic status when AF develops.106

Finally, AF complicating acute MI is also associated with an increased risk of subsequent ‘spontaneous’ AF, and also with an increased risk of ischaemic stroke both during hospitalization and during follow-up; even if the AF is transient and reverses back to sinus rhythm before hospital discharge.106

Literature evidence for the management of AF in the setting of acute MI stemming from controlled clinical trials is lacking, so the treatment is essentially founded on practical basis.

In many cases, the arrhythmia is well tolerated and no specific treatment is required.

In other instances, the high ventricular rate associated with AF may contribute to hemodynamic impairment and heart failure, requiring prompt therapeutic intervention. Adequate rate control represents the most important first therapeutic approach in this setting, and may be accomplished either by administration of beta-blockers or possibly non-dihydropyridine calcium antagonists, either orally or intravenously. In patients with acute MI and AF associated with severe LV dysfunction or heart failure, the negative inotropic effect of beta-blockers or calcium antagonists may result in further impairment of pump function. In such circumstances, rate control may be achieved by intravenous administration of amiodarone and/or digitals.107

Urgent DCCV is recommended for patients with severe hemodynamic instability or intractable ischaemia, or when adequate rate control cannot be achieved with pharmacologic agents. In this latter case, transesophageal echocardiography should be considered to exclude the presence of thrombi in left atrium. In addition to electrical CV, amiodarone can be used for restoration of sinus rhythm when the hemodynamic situation is stable. This drug is usually preferred to other AADs because of its limited negative inotropic effect. The administration of class IC AADs, instead, is considered harmful in patients with acute MI and hence is not recommended.108,109

In the post hoc analysis in patients with coronary heart disease and atrial fibrillation from the ATHENA (A placebo-controlled, double-blind, parallel arm Trial to assess the efficacy of dronedarone 400 mg b.i.d. for the prevention of cardiovascular Hospitalization or death from any cause in patients with Atrial fibrillation/atrial flutter) trial, dronedarone reduced all-cause mortality, cardiovascular hospitalization, and the first ACS event. However, experience with dronedarone in the setting of ACS is limited, and the drug is not recommended for thus indication.110

Finally, patients with AF and moderate-to-severe thromboembolic risk (CHA2DS2-VASc score ≥2) should be adequately treated with oral anticoagulants (either vitamin K antagonists or new oral anticoagulants) to reduce the risk of stroke or systemic embolisms (see below).

Recommendations for the management of atrial fibrillation in acute coronary syndrome

- For patients with acute coronary syndrome and pre-existing or newly developed atrial fibrillation (AF), rate control using beta-blockers or possibly calcium antagonists is recommended, whereas in patients with severe LV dysfunction using amiodarone and/or digitals is recommended.
- Urgent direct current cardioversion is required if AF is accompanied by hemodynamic instability.
- For restoration of sinus rhythm in addition to electrical cardioversion amiodarone can be considered. Other antarrhythmic drugs might be harmful in the setting of acute myocardial infarction.
- Adequate anticoagulation according to the individual risk of stroke and embolism is recommended, usually requiring a period of combination therapy of antiplatelet agents and anticoagulants.

Risk assessment for thromboembolic events, bleeding, and choice of antithrombotic therapy in patients with atrial fibrillation and acute coronary syndrome

Patients with ACS and permanent, paroxysmal or persistent non-valvular AF are a special subgroup with an increased risk for ischaemic and embolic events, as well as bleeding complications. Since these events are closely related to clinical outcomes including mortality,
decision making in the individual patient should be made by taking into account the risk for thromboembolic and bleeding hazards alike.

**Stroke risk stratification**

Based on the recent ESC guidelines stroke risk stratification should be made by the CHA₂DS₂-VASc score, which means that all patients with ACS will have a score of at least 1 and will therefore be candidates for oral anticoagulation. Patients with STEMI usually are treated with primary PCI and stenting in over 90% of cases, while PCI will be performed in about 50–60% of patients presenting with non-ST elevation ACS. Both groups of patients have an indication for dual antiplatelet therapy (DAPT). Hence, ‘triple’ therapy (DAPT and oral anticoagulation) for a defined period after the event is usually required. One controlled trial suggested that therapy with clopidogrel and an oral anticoagulant could be slightly safer than ‘triple therapy’, but more data are needed to confirm this.

**Bleeding risk stratification**

Patients with an increased thromboembolic risk usually have clinical characteristics that are also associated with increase bleeding tendency, i.e. advanced age, female gender, renal dysfunction, femoral access, and history of prior bleeding hazards, especially of peptic ulcer. Accordingly, the use of specific risk scores (HAS-BLED score) to stratify for bleeding tendency in patients with AF seems practicable. In AF patients with and without anticoagulation therapy, it has higher accuracy in prediction of bleeding events and easier to use as compared with other scores. In patients with ACS, receiving triple antithrombotic therapy HAS-BLED score was found to have diagnostic value in prediction of bleeding.

HAS-BLED score is currently recommended for risk stratification of bleeding in patients with AF and ACS.

**Choice of antithrombotic therapy based on thrombosis and bleeding risks**

When AF affords anticoagulation in addition to DAPT, ‘triple’ antithrombotic therapy (DAPT plus an anticoagulant, usually a vitamin K antagonist (VKA) with an INR goal of 2.0–2.5) is recommended for the shortest time necessary, which is usually 1 month after bare metal stents and 3 (–6) months after drug-eluting stent in stable/elective patients as well as 6 months after ACS independent of the stent type and treatment strategy used, followed by one antiplatelet agent (clopidogrel or aspirin) plus an anticoagulant (‘dual’ therapy) for up to 12 months, and then by anticoagulant monotherapy lifelong.

VKAs were shown to be at least as effective as aspirin in secondary prevention after acute MI. Ongoing research and expert-based position papers might widen the indication for non-VKA oral anticoagulants (NOACs) as replacement for VKAs in this clinical setting in the near future.

**Recommendations for risk assessment for thromboembolic events, bleeding and choice of antithrombotic therapy in patients with atrial fibrillation and acute coronary syndrome**

- In patients with acute coronary syndrome and atrial fibrillation, prevention of thromboembolic events should be based on individualized risk stratification of thromboembolic events (risk of stroke-CHA₂DS₂-VASc score) to define the need for anticoagulation, risk stratification of bleeding (HAS-BLED score) to define the level of anticoagulation or choice of non-vitamin K antagonist oral anticoagulant strategy, and measures to minimize bleeding complications (stent choice, radial approach, and consequent short- and long-term dual antiplatelet therapy).

**New bundle branch block and atrioventricular conduction disorders as complication of myocardial infarction**

Atrioventricular conduction disturbances are well-known complications of acute MI. During the first few hours of myocardial ischaemia, they may be related to an autonomic imbalance with a vagal hyperactivity leading to a transient slowing of AV conduction.
Myocardial ischaemia and necrosis may induce transient dysfunction or irreversible damage of the AV conduction system that may lead to the development of a new bundle branch block (BBB) or worsen a symptomatic high degree AV block necessitating temporary or permanent cardiac pacing.

In order to fully understand the relationship between myocardial ischaemia-infarction and the occurrence of new AV conduction disturbances, it is important to review the vascular supply of the different parts of the conduction system. The AV node and also the His bundle are supplied by the AV nodal artery that takes origin from the RCA in a 90% of the cases and from the left circumflex artery in 10% of the patients. A post mortem study has shown that proximal left anterior descending coronary artery (LAD) septal perforators perfuse the right bundle branch and the anterior fascicle of the left bundle branch in 90% of cases, whereas the posterior fascicle of the left BBB is perfused by the conus branch of the RCA in the majority of the cases. There is dual blood supply to each of the fascicles in half of the patients. An occlusion of the LAD therefore will induce a right BBB or an anterior left fascicular block. The development of a new left BBB will occur only in the presence of a proximal occlusion of both the RCA and the LAD.

A second or third degree AV block in patients with an acute inferior wall MI is almost always (90% of the patients) located above the His bundle. Most often, this only results in a moderate bradycardia with a junctional escape rhythm with narrow QRS complexes. This conduction disorder most frequently is transient and is associated with a low mortality risk.

In patients with an anterior wall MI, a high degree AV block is most often located below the AV node. Total AV block generally occurs abruptly during the first 24 h after MI and is frequently preceded by the development of a new right BBB with the right or left axis deviation and QR pattern in lead V1. Most often, it is associated with an extensive myocardial necrosis of the septum and anterior wall in the presence of severe multivessel disease involving both the LAD and the RCA or a dominant left circumflex artery. Usually it causes catastrophic hemodynamic problems frequently leading to lethal pump failure.

Patients with a BBB have more comorbidities and are less likely to receive timely reperfusion therapy. It remains uncertain if the presence of a BBB at presentation has a prognostic importance. After adjustment for confounding factors, the presence of a BBB was no longer associated with an increased mortality risk. However, patients who develop a new left BBB within 60 min after admission have a three times higher 30-day mortality.

**Recommendations for management of new bundle branch block and atrioventricular conduction disorders in acute coronary syndrome**

- Prompt opening of the infarct vessel is often sufficient to reverse new-onset ischaemic conduction disturbances. This is especially true for atrioventricular (AV) block in the setting of inferior infarctions.
- Temporary pacing is indicated for symptomatic life-threatening bradycardia not resolving after successful reperfusion and after medical treatment in the presence of high-degree AV block and intraventricular conduction defects.
- Permanent pacing is considered for disturbances that persist beyond the acute phase after the myocardial infarction.

**Temporary pacing in intensive cardiac care unit in patients presenting with acute coronary syndrome: indications and techniques**

**Temporary pacing in cardiac intensive care unit**

Temporary endocardial pacing has been used since the early 1960s to maintain cardiac output during episodes of extreme bradycardia, AV block, and asystole. Before the advent of cardiac pacemakers (PMs), the combination of acute MI and complete AV block was usually fatal, but now pacing electrodes can be safely placed percutaneously into the right ventricle under local anaesthesia. Prognosis is influenced not only by complications of the procedure, but also by the underlying myocardial damage, which originally lead to the conduction defect. In patients, who have not suffered an acute MI and are admitted to cardiac intensive care unit, temporary pacing may be required for treatment of asystole or bradycardia due to primitive cardiac conduction diseases, drug toxicity, electrolyte disturbances, or surgery.
Techniques for temporary pacing
Endocardial temporary pacing leads are introduced via a central vein: right interior jugular, right subclavian vein or femoral veins. Pacing wires are commonly 5F or 6F. Under fluoroscopy, the lead is advanced into the right atrium and then, crossing the tricuspid valve, placed at the right ventricle apex. A check for positional stability, asking the patient to take some deep breaths or cough forcefully and watch for failure of capture, is suggested. A chest X-ray to confirm satisfactory positioning of the wire and to exclude a pneumothorax, is recommended as well.

Following cardiac surgery, patients may have temporary epicardial electrodes in case of postoperative bradycardia. These are used in the same way as transvenous pacing leads, but the threshold may be higher.

In emergency situations, transthoracic pacing is a better alternative, although it is not a substitute for temporary transvenous PM, and represents only a bridge to maintain life.

Complications
A temporary PM is a foreign body that may remain in the circulation for days and has a high propensity for infections, thus requiring surgical asepsis and antibiotic prophylaxis. Moreover, in case of a femoral approach for temporary pacing, restricted patient mobility may be cause of asymptomatic deep vein thrombosis, therefore antithrombotic prophylaxis as well is recommended.

The main frightening complication of temporary pacing in an ACS setting is the cardiac perforation causing cardiac tamponade. The incidence of complications and malfunctions may be significant, occurring within 24 h in about 50% of patients and within 48 h in 86% of patients. Failure to capture or sense, VT during catheter insertion, fever and phlebitis are the most common complications. Other possible, more rare ones include phrenic capture, vascular complications for femoral approach (hematoma, pseudoaneurysm, arteriovenous fistula), hemotherax, and pneumothorax for subclavian and jugular accesses, cardiac perforation and tamponade. Sepsis, phlebitis, and pulmonary embolus are more common with temporary PMs in place for 72 h or longer. In many patients, particularly after acute MI, placing a pacing lead within the right ventricle will promote ventricular ectopic activity and occasionally prolonged VA. These will usually resolve once manipulation of the lead has ceased but will occasionally require removal of the lead or repositioning.

An eventual cardiac perforation is usually manifest by raised pacing thresholds and occasionally by pericarditic pain and a pericardial friction rub. At worst, this will result in cardiac tamponade and will require appropriate urgent treatment. The increased risk of cardiac perforation and tamponade may be related to several factors such as (1) the emergency setting; (2) not-specialist doctors inserting the wire; (3) higher stiffness of the leads; (4) concomitant use of potent antithrombotics (GP IIb/IIIa inhibitors); (5) inferior MI (with frail wall).

Recommendations for temporary pacing in intensive cardiac care unit in patients presenting with acute coronary syndrome: indications and techniques

- Temporary transvenous pacing should not be used routinely and only as a last resort when positive chronotropic drugs (e.g. isoproterenol, atropine, etc.) are insufficient or contraindicated.
- Temporary transvenous pacing should be limited to cases of (i) high-degree atioventricular block without adequate escape rhythm; (ii) life-threatening bradycardias, such as those that occur during interventional procedures (e.g. during percutaneous coronary intervention) or, rarely, in acute settings such as acute myocardial infarction, drug toxicity, electrolyte disturbances, or concomitant systemic infection.
- If the indications for permanent pacing are established, every effort should be made to implant a permanent pacemaker as soon as possible.
- An external stimulator (transcutaneous) does not provide reliable ventricular stimulation and therefore should only be used, under strict haemodynamic and electrocardiographic monitoring, when no other option is available. As soon as possible, an alternative action should be undertaken (administration of chronotropic drugs or temporary or permanent pacing).

Electrical cardioversion for arrhythmias in acute coronary syndrome patients with implanted rhythm devices
The different techniques for electrical CV depend on the various types and positioning of paddles, energy strategies and waveforms used. When performed in patients with an implanted PM and ICD systems, the choice between the different techniques can affect the outcome and safety of a CV.

When using biphasic defibrillators, self-adhesive defibrillation pads are safe and effective and an acceptable alternative to standard defibrillation paddles for both defibrillation and CV. The majority of studies comparing paddle size orientations and positioning (anterior-apex, anterior-posterior, anterior-left infrascapular, anterior-right infrascapular) have shown equal effectiveness in defibrillation (for VAs) or elective AF CV success, although an anterior-lateral electrode position was reported to increase efficacy and require fewer shocks for common atrial flutter. In recent resuscitation guidelines, an anterior-posterior position is generally accepted as an alternative position to an anterior-lateral position.

The numerous case reports on device and lead failure following external CV in patients with implanted PM systems, has led to certain precautions including paddle positions to increase the safety of the procedure.

The risk of damage to the device is minimized by diodes that shunt current away from device and may be further reduced by keeping maximal distance between shock electrodes and the device. Leads may not be protected by these measures and current density may increase at the lead tip, particularly with unipolar leads, leading to myocardial damage at the electrode–endocardial surface. Such damage...
may result in local myocardial oedema with a transient increase of pacing threshold and fibrosis with permanent progressive increased pacing threshold and a deterioration of sensing function. These observations thus further argue for an anterior-posterior position for CV and also for defibrillation in patients with devices.

Very few studies have analysed the safety of external CV in patients with implanted PM systems.140 Transient loss of capture (up to 30 min) occurred in 50% of patients, a six-fold increase of ventricular pacing thresholds, sensing failure in 41% of patients, and three cases of PM malfunction were reported in a study evaluating patients with PM devices implanted in the right pectoral region and with unipolar electrodes.141 It was concluded that CV represents a serious hazard to patients with an implanted PM. In that study, however, only monophasic shocks were used and placed in an anterior-lateral orientation, which may create an electrical field in the same direction as the ventricular lead. An anterior-posterior positioning of CV electrodes is superior as it prevents this ‘antenna-like effect’ of the ventricular lead and result in lower energy requirements for termination of AF.145 Since biphasic shocks are superior to monophasic shocks for CV of AF42 and in terminating VF, all new defibrillators deliver shocks using biphasic waveforms. Mono- and biphasic shock waveforms for external CV were recently compared with regard to safety and efficacy in a prospective study of patients with implanted devices.143 Lower energy levels and at least >8 cm distance to the implanted device were adopted to minimize risk for damage to the devices and leads. Systems were tested immediately before and after CV, and 1 h and 1 week later with respect to device and lead integrity. Pacing impedances were reduced immediately after CV and returned to baseline values within 1 week. Ventricular sensing was reduced immediately after CV. There was no device or lead dysfunction in any patient. Cardioversion was successful in 95% of patients. The lower cumulative energy requirement for biphasic as compared with monophasic shocks indicated a theoretical advantage for biphasic shocks.

Electrical CV can thus be safely and effectively performed in patients with implanted rhythm devices, if the precautions outlined are considered. These recommendations also apply to emergency situations of VA in patients with implanted devices.

Conclusion

This document summarizes the current position, contemporary approaches, and offers recommendations on how to identify ACS patients at risk for arrhythmias; manage tachyarrhythmias and bradycardiac arrhythmias using pharmacological and non-pharmacological, device- and catheter-based approaches including electrical CV, implantation of temporary PMs, programming of ICD, catheter ablation; and implement clinical and referral strategies. These recommendations are provided for acute care and management of VA, AF, bradycardiac arrhythmias, and prevention of stroke and embolism in patients with ACS, and arrhythmias developing during coronary interventions, in patients with implanted devices and cardiogenic shock. Management of intractable arrhythmias requires the team-based approach including specialists in acute cardiac care, interventional cardiology, and electrophysiology.

Further supportive to the current knowledge evidence on the specific issues of arrhythmias management in the setting of ACS and answers to the gaps in knowledge emphasized in the current document should be pursued in future studies.
